Like many animals, firebugs (Hemiptera, Pyrrhocoridae) rely on behavioural adaptations to successfully endow their offspring with microbial mutualists. To transmit the nutritionally beneficial Coriobacteriaceae symbionts, female firebugs smear egg surfaces with symbiont-containing faecal droplets that are subsequently ingested by newly hatched nymphs through active probing to initiate infection. Alternatively, the symbionts can be acquired horizontally through contact with faeces of infected conspecifics. Here, we report that these adaptations ensuring successful transmission of bacterial symbionts among firebugs are exploited by the specialized trypanosomatid parasite Leptomonas pyrrhocoris. Using comparative transcriptomics, fluorescence in situ hybridization (FISH) and controlled bioassays, we demonstrate that the transmission cycle of L. pyrrhocoris mirrors that of the bacterial mutualists, with high efficiency for both vertical and horizontal transmission. This indicates that the parasite capitalizes on pre-existing behavioural adaptations (egg smearing and probing) to facilitate its own transfer within host populations, adaptations that likely evolved to initiate and maintain an association with beneficial gut symbionts. Thus, the transmission of mutualistic microbes across host generations can entail a significant risk of co-transmitting pathogens or parasites, thereby exerting selective pressures on the host to evolve more specific mechanisms of transfer.

1. Introduction

Mutualisms with microorganisms have played an integral role in the evolution of animals [1]. As such, numerous adaptations have evolved, in both host and symbiont, to ensure the successful transfer of beneficial microbes to future host generations [2], thereby contributing to the maintenance and evolutionary stability of mutualisms. Similarly, among parasites that obligately depend on their hosts for survival, fitness is largely determined by their success in establishing infection and transmitting to other hosts [3]. Thus, adaptations for successful initiation and maintenance of infection are strongly selected for, and, as a result, represent a fundamental component of the parasites’ ecology and evolution [4].

Firebugs associate with a highly stable gut bacterial community dominated by two actinobacterial symbionts belonging to the Coriobacteriaceae family, as well as members of the Firmicutes and Gammaproteobacteria [5,6]. The two Coriobacteriaceae symbionts Coriobacterium glomerans and Gordonibacter sp. are vertically transmitted across host generations through the faecal smearing of egg surfaces by females during oviposition, but can also be horizontally acquired through contact with conspecifics [7]. Experimental sterilization of egg surfaces disrupts the transmission cycle of the Coriobacteriaceae symbionts, resulting in aposymbiotic (symbiont-free) firebugs that suffer retarded growth, high mortality and low fecundity [8], which is owing to the deficiency in B vitamins that are provided by the symbionts [9].
Matching the highly conserved bacterial midgut community associated with firebugs is the specialized epidemiology of trypanosomatids across this insect family [10]. Most striking is the cosmopolitan distribution of a single, mildly virulent flagellate, *Leptomonas pyrrhocoris*, across at least 11 species and four genera of firebugs sampled from eight countries across four continents [10–12]. Among firebugs, infection by *L. pyrrhocoris* can induce paler coloration, lethargy and diarrhoea [11], as well as increased mortality, reduced starvation resistance and a reduced lifespan in insects that contract the parasite early in development [12].

Despite the global distribution of *L. pyrrhocoris* among firebugs, little is known about how infection is initiated and maintained. While it is presumed that *L. pyrrhocoris* is horizontally transferred between con- and heterospecifics as mediated by the large aggregations formed by the insects [10], no study to date has directly reported on the transmission route of *L. pyrrhocoris* within and between host populations.

In this study, we demonstrate that the transmission route of *L. pyrrhocoris* in firebugs mirrors that of the Coriobacteriaceae symbionts. Specifically, we report that while *L. pyrrhocoris* can be acquired horizontally through contact with infected firebugs, the parasite also exploits the symbionts’ vertical transmission route via the egg surface for its own transfer among host individuals.

2. Results and discussion

Our first insights into the transmission route of trypanosomatids in pyrrhocorid bugs came from comparative transcriptomic analyses of midguts extracted from the firebug *Dysdercus fasciatus* that had either been subjected to egg surface sterilization to rid them of their beneficial Coriobacteriaceae symbionts or left untreated. While the untreated group featured transcripts that could be assigned to the Trypanosomatidae cluster TU61 (associated with the genus Blastocrithidia, see [10]), none could be retrieved from firebugs that had been subjected to egg surface sterilization (figure 1a), suggesting that the method for eliminating the bacterial symbionts also clears infection by the trypanosomatid. This hypothesis is corroborated by fluorescence in situ hybridization (FISH) images demonstrating the co-localization of *L. pyrrhocoris* and *C. glomerans* in faecal droplets collected from firebugs that had been artificially inoculated with *L. pyrrhocoris* in the laboratory (figure 1b).

To directly test for the vertical and horizontal transmission routes of *L. pyrrhocoris* in *D. fasciatus*, we harvested six egg clutches from *L. pyrrhocoris*-infected mating pairs and divided the eggs of each clutch into four groups: (i) untreated, (ii) egg surface-sterilized, (iii) egg surface-sterilized, followed by the inoculation of *L. pyrrhocoris* from pure culture over egg surfaces, and (iv) egg surface-sterilized, then reared upon hatching in the presence of two *L. pyrrhocoris*-infected adult *D. fasciatus*.

Matching the infection dynamics of the Coriobacteriaceae symbionts (figure 2a,b), *L. pyrrhocoris* (figure 2c) could be detected with high prevalence in the untreated group (82%). In contrast, the sterilization of egg surfaces resulted in adult firebugs that completely lacked the symbionts as well as *L. pyrrhocoris* (figure 2a–c; \( p < 0.001, \chi^2 \text{ test} \)). Spreading cultured *L. pyrrhocoris* over previously sterilized eggs reestablished the infection at a high frequency (63%; figure 2c), thereby confirming that the parasite can vertically transmit via the egg surface. Additionally, horizontal transfer of *L. pyrrhocoris* among conspecifics occurred with high efficiency (100%) in firebugs that were subjected to the egg surface sterilization procedure but were subsequently reared in the presence of infected conspecifics (figure 2c). Collectively, such findings demonstrate that *L. pyrrhocoris* is transmitted across host generations in a manner that is identical to the beneficial Coriobacteriaceae symbionts [7]: vertically via the egg surface and horizontally through contact with infected firebugs, specifically their faeces (figure 2a,b). This is consistent with recent findings in milkweed bugs and their trypanosomatid parasite, *Leptomonas wallacei* [13], where transovum propagation of the parasite was demonstrated to mediate vertical transmission. Despite the parallels to the transmission cycle of *L. pyrrhocoris*, it is unclear whether the egg probing behaviour in *Oncopeltus fasciatus* is relevant for symbiont transmission, considering the lack of evidence for vertically transmitted mutualists associated with milkweed bugs [14].

When examining parasite titres among infected individuals across the three *L. pyrrhocoris*-harbouring treatments (figure 2d), we found that parasite load was significantly different across groups (\( p = 0.012, \text{Kruskal–Wallis } H \text{-test} \)). Specifically, *D. fasciatus* reared in the presence of infected firebugs were found to harbour higher titres of *L. pyrrhocoris* compared with treatments where the trypanosomatids
were provisioned over the egg surface, possibly as a consequence of repeated exposure to the parasite via contact with infected conspecifics.

The transmission dynamics reported in this study for *L. pyrrhocoris* are consistent with theoretical predictions implicating bimodal (horizontal and vertical) transfer, alongside low virulence, as hallmarks of globally distributed, specialized parasites [3]. Additionally, the high vertical transmission efficiency of the parasite may ultimately select for reduced virulence [15], owing to the alignment of interest in host and parasite, which may explain the predominance of asymptomatic infections caused by trypanosomatids in insects [16].

Many parasites exploit the ecology of their hosts to initiate infection. For example, *Crithidia bombi*, the trypanosomatid parasite of bumblebees, capitalizes on its host’s social organization to spread among nest-mates following contact with infected individuals [17]. *C. bombi* can also propagate within populations of its hosts through the shared use of flowers [18], collectively highlighting the adaptive propensity of the parasite to the behavioural as well as feeding ecology of bumblebees. Coprophagy, which often not only contributes towards fulfilling the nutritional requirements of immature insects [19], also facilitates the horizontal transfer of trypanosomatids across a range of bug species [16]. In this study, however, we report on how a specialized parasite may have capitalized on pre-existing adaptations for mutualist transmission in an insect to facilitate its own transfer, thereby contributing to a cosmopolitan distribution mirroring that of the host [10] as well as of the beneficial bacterial associates of this insect family [6]. Given the widespread occurrence of extracellular symbiont transmission routes in insects [2], in particular through the smearing of egg surfaces with faeces or glandular secretions, co-transmission of intestinal parasites is likely a common phenomenon. Hence, the risk of parasite hitchhiking may result in trade-offs that favour the evolution of additional mechanisms ensuring specificity during transfer by the host or new defences against the parasite, particularly if the

costs of parasite infection outweigh the benefits of acquiring mutualistic microbes.

3. Material and methods

(a) Insect sampling and rearing

Live *D. fasciatus* were originally collected in the Comoé National Park, Côte d’Ivoire, but have since been maintained in the laboratory at the University of Würzburg, Germany, and a subculture was later established at the Max Planck Institute for Chemical Ecology, Jena, Germany. The insects were reared in plastic containers (20 × 35 × 22 cm) at a constant temperature of 28°C and exposed to long light regimes (16 h L : 8 h D cycles).

(b) Illumina-based transcriptome sequencing

RNA was extracted from dissected whole midgut regions (M1–M4) from five symbiotic and aposymbiotic bugs, respectively, resulting in two pooled samples. Transcriptome sequencing of poly-A enriched mRNAs, assembly, annotation and analysis were described previously [9,20]. The sequence data were deposited in the European Nucleotide Archive, accession number PRJEB6171 (http://www.ebi.ac.uk/ena/data/view/PRJEB6171).

(c) Fluorescence in situ hybridization

Faecal droplets were collected from infected adults by pressing the insect’s abdomen on a glass slide. Upon drying, the faeces were fixed with 70% and 99% ethanol in succession. Cor633 [7] and in situ (c) probes were used to screen for the parasite, using the following cycle parameters: 3 min at 94°C, followed by 32 cycles of 94°C for 40 s, 56°C for 1 min and 72°C for 1 min, and a final extension time of 4 min at 72°C. Screening for *C. glomerans* and *Gordonibacter* sp. was performed as previously described [8], using the primers Cor2F/Cor1R and fD1/Egg1R, respectively.

(d) Experimental set-up

Six egg clutches (approx. 30 eggs each) from different females of *L. pyrrhocoris* were reared in contact with two infected adults. Egg clutches were collected into four experimental treatments: (i) untreated, (ii) surface-sterilized, (iii) surface-sterilized then re-infected with a pure inoculum of *L. pyrrhocoris* (30 µl of approx. 10^8 flagellates µl^-1) and (iv) surface-sterilized and subsequently reared in contact with two *L. pyrrhocoris*-infected adult bugs. The four treatments were provided ad libitum with autoclaved water and a nutrient-rich artificial diet [9].

The sterilization of egg surfaces followed the procedure used in [8]. Briefly, the eggs were submerged in ethanol for 5 min, followed by bleach (12% NaOCl) for 45 s. Residual bleach was removed by washing in autoclaved water.

(e) DNA extraction and PCR screening for *Leptomonas pyrrhocoris* and the Coriobacteriaceae symbionts

All individuals from every experimental treatment were subjected to DNA extraction three days after adult emergence as previously described [8]. Primers targeting *L. pyrrhocoris* 18S rRNA gene, SSU Fwd2 (5’-CTGGTTGATCTGCCAGTAGT-3’) and SSU Rev2 (5’-GAGTCAACACTGCTGGTGTT-3’) were then used to screen for the parasite, using the following cycle parameters: 3 min at 94°C, followed by 32 cycles of 94°C for 40 s, 56°C for 1 min and 72°C for 1 min, and a final extension time of 4 min at 72°C. Screening for *C. glomerans* and *Gordonibacter* sp. was performed as previously described [8], using the primers Cor2F/Cor1R and fD1/Egg1R, respectively.

(f) Quantitative PCR

To assess parasite infection titres, quantitative PCR for *L. pyrrhocoris* was conducted for samples that were positive for the parasite per diagnostic PCR, using aRotorGene-Q cycler (Qiagen, Hilden, Germany). The final reaction volume of 25 ml included the following components: 1 ml of DNA template, 2.5 ml of SSU Fwd2 and SSU Rev2 primers (10 mM), 6.5 ml of autoclaved distilled H2O and 12.5 ml of SYBR Green Mix (Qiagen, Hilden, Germany).

(g) Statistical analysis

Infection rates of *L. pyrrhocoris*, *C. glomerans* and *Gordonibacter* sp. across the four experimental treatments were compared using pairwise χ² tests (SPSS, Chicago, IL). To compare *L. pyrrhocoris* 18S copy numbers estimated in the qPCRs, Kruskal–Wallis H-test with Dunn’s post hoc comparisons was used as implemented in BiAS v. 7.40 (Epsilon Verlag, Hochheim-Darmstadt, Germany).

Ethics. The work conducted complies with the ethical regulations in Germany.

Data accessibility. Original data on PCR and qPCR results of symbiont and parasite infection are available in the Dryad Digital Repository at http://dx.doi.org/10.5061/dryad.187mt.

Authors’ contributions. H.S., T.O.O. and M.K. conceived of the study. T.O.O. and M.K. performed the experiments. H.S. analysed the data. E.B. performed the transcriptomic analysis. H.S. drafted the manuscript, and all authors reviewed, approved and are accountable for the final version for publication.

Competing interests. The authors declare that they have no competing interests.

Funding. Financial support from the Max Planck Society (H.S., T.O.O., M.K.) and the Jena School for Microbial Communication (to T.O.O.) is gratefully acknowledged.

Acknowledgements. We thank Benjamin Weiss for his assistance in caring for the bugs, and Jan Votýpka for providing a pure culture of *L. pyrrhocoris*.
