Dated phylogenies of fossil taxa allow palaeobiologists to estimate the timing of major divergences and placement of extinct lineages, and to test macroevolutionary hypotheses. Recently developed Bayesian ‘tip-dating’ methods simultaneously infer and date the branching relationships among fossil taxa, and infer putative ancestral relationships. Using a previously published dataset for extinct theropod dinosaurs, we contrast the dated relationships inferred by several tip-dating analyses and evaluate potential downstream effects on phylogenetic comparative methods. We also compare tip-dating analyses to maximum-parsimony trees time-scaled via alternative a posteriori approaches including via the probabilistic cal3 method. Among tip-dating analyses, we find opposing but strongly supported relationships, despite similarity in inferred ancestors. Overall, tip-dating methods infer divergence dates often millions (or tens of millions) of years older than the earliest stratigraphic appearance of that clade. Model-comparison analyses of the pattern of body-size evolution found that the support for evolutionary mode can vary across and between tree samples from cal3 and tip-dating approaches. These differences suggest that model and software choice in dating analyses can have a substantial impact on the dated phylogenies obtained and broader evolutionary inferences.

1. Introduction

How fossil organisms are related to each other and to living lineages is a matter of interest both to the general public and the scientific community. This matter surpasses systematic placement, because our estimates of branching relationships and their timing have direct implications on macroevolutionary inferences. Few examples are better than Archaeopteryx, which has long caught public attention as a potential early bird, a position questioned by a recent maximum-parsimony phylogenetic analysis [1] but seemingly reaffirmed by a later maximum-likelihood analysis [2].

Parsimony versus model-based phylogenetics is only one great debate in palaeontological systematics: for decades, there has been disagreement about whether to consider stratigraphic occurrences when inferring relationships [3]. Recently, the oft-criticized parsimony-based ‘stratocladistics’ [4] has been reborn as Bayesian ‘tip-dating’ phylogenetics [5], where non-ultrametric time-scaled phylogenies of extinct fossil tip taxa are inferred as a function of both clock-like models of character
change and a tree prior, describing the distributions of divergence dates [6,7]. Most recently, these tree priors belong to the birth–death-serial-sampling (BDSS) family of models, which involve both diversification and sampling processes in the fossil record [8]. Tip-dating with BDSS is implemented in Bayesian phylogenetics applications, such as BEAST2 and MrBayes, including allowing for fossil taxa to be considered as potential sampled ancestors [9,10]. Sampled-ancestor BDSS (‘SA-BDSS’, also known as sampled-ancestor-birth–death or fossilized-birth–death) models [11] differ from non-sampled-ancestor BDSS (noSA-BDSS) or transmission birth–death process, where sampling is synchronous with extinction [12]. Fossilization is unlikely to coincide with extinction, and thus noSA-BDSS may be more fitting to pathogen phylogenetics in epidemiology. Additionally, paleobiologists often use a posteriori time-scaling (APT) to secondarily date existing cladograms of extinct taxa. While some APT methods are arbitrary rescaling algorithms, the $cal3$ approach probabilistically dates divergences relative to an SA-BDSS variant [13].

The diversity of approaches, models and software that can be used to obtain a fossil-only time-scaled phylogeny calls for an empirical comparison of tip-dating and probabilistic APT methods. We choose to perform such an examination using the matrix from Xu et al. [1], paired with stratigraphic occurrences. Although this matrix was outdated by later revisions [14], its usage in studies employing different phylogenetic methods makes it an attractive basis for a case study comparing the results of dating approaches, which differ in the model assumed and their implementation. Analysing the original Xu et al. matrix also allows us to test whether Bayesian tip-dating avoids atypical relationships [15,16] inferred by Lee & Worthy [2]. Additionally, the emergence of avian dinosaurs has been a focus for macroevolutionary studies [17], and thus, we can use this dataset to examine how different dating methods impact downstream phylogenetic comparative methods.

2. Material and methods

We used the 374 character matrix for 89 taxa from [1] and age data from the Paleobiology Database for a series of Bayesian tip-dating analyses using BEAST2 and MrBayes. We performed analyses with noSA-BDSS as the tree prior using BEAST v. 2 [12] and SA-BDSS with both programs [9,10]. All tip-dating analyses used the Mk2 model of character change [18] and accommodated stratigraphic uncertainties in first appearances of tip taxa as uniform priors. We applied minimum-age and minimum-branch-length APT approaches to 100 randomly selected most-parsimonious trees (MPTs) with first appearance times used as tip dates, including $cal3$ [13] with input rates taken from the BEAST2 SA posterior estimates to maximize the comparability of our analyses. We compared divergence dates and ancestral placements between samples of 100 APT-dated MPTs to a random selection of 100 post-burn-in trees from the Bayesian analyses. We also used these samples to compare the outcomes of a comparative analysis, mimicking the analyses of [17], fitting models for Ornstein–Uhlenbeck (OU), early burst (EB), and Brownian motion (BM; via $gi€\lger$) [19]. Further details of our methods and convergence assessments for the tip-dating analyses are in the Methods section of the electronic supplementary material.

3. Results

The relationships inferred under the Bayesian methods are similar to previous analyses [1,2]. In the BEAST2 analyses, $Archaeopteryx$ has a posterior probability of 1 of being a member of the branch-defined Avialae ( electronic supplementary material, figures S6–S7), in agreement with [2] (and contrary to Xu et al. [1]). However, MrBayes SA gives a posterior probability of 0.68 for the same placement (electronic supplementary material, figure S8). The unexpected relationships found by the maximum-likelihood study [15,16] are avoided, although the placements of the Alvarezsauridae and Scansoriopterygidae can vary considerably with strong support (see electronic supplementary material, Results). For example, all tip-dating analyses find a monophyletic Tyrannosaurusriccia with high support (no posterior probability less than 0.97).

Although sampling theropod ancestral taxa may seem unlikely, both SA tip-dating analyses generally inferred a median of 1–2 ancestors per tree (this frequency was skewed in MrBayes, with some trees containing up to 33 sampled ancestors). Both BEAST2 and MrBayes SA analyses place similar sets of taxa as ancestors (electronic supplementary material, figure S3), with a strong rank-order correlation of the per-taxon frequencies of ancestor placement (Spearman $p = 0.69$, $p$-value = $5.31 \times 10^{-14}$). The $cal3$ analyses using first appearances never infer any ancestors, but similar correlations were found with ancestor frequencies from $cal3$ using last appearance times (see electronic supplementary material, Results).

While $Archaeopteryx$ is popularly referred to as an ‘ancestral bird’, it is a sampled ancestor in only 5% of the MrBayes posterior (0% for BEAST2 SA), and then only to its close relative $Wuthwormiria$, not the more nested Avialae.

Comparisons of divergence dates for four nested avian clades (using a branch-based definition) show differences in clade age estimates across approaches (figure 1). All APT methods propose similar median ages for all four clades, much younger than tip-dating estimates. This is due to maximum-parsimony analyses placing the early-appearing $Evidentixiertorx$ and $Epidendosaurus$ (i.e. the Scansoriopterygidae) as members of a branch-based Avialae (also observed in [1,2]), which constrains the age of the Avialae to the Middle Jurassic or older. Tip-dating analyses vary in their placement of the Scansoriopterygidae but do not place them with the Avialae (see electronic supplementary material, Results). Divergence date estimates from $cal3$ for alternative non-Avian clades (Tyrannosauroidia, Therizinosauroidea) resemble distributions obtained from tip-dating (electronic supplementary material, figure S1), illustrating how APT approaches are ultimately constrained by input topologies. Even among tip-dating methods, there are differences, with BEAST2 noSA estimating earlier root ages than SA analyses, and BEAST2 SA having wider age distributions than MrBayes SA. Comparing age estimates for clades containing identical taxa reveals that tip-dating approaches estimate median divergence dates approximately 4–6 million years (myr) older than the earliest stratigraphic occurrence, although root-ward nodes have median ages as much as 30–40 myr older (see electronic supplementary materials, Results).

The original body-size analysis [17] used several APT approaches, including the 1 myr minimum-branch-length (MBL) approach. Under all time-scaling variants, they found strong support for single-optima OU for Theropoda and Maniraptora. Our reanalysis with alternative dated phylogenies agrees, with high support for OU across all approaches, particularly MBL (figure 2). However, our analysis reveals that model support varies considerably across trees from the same dating approach, with some phylogenies
providing greater support for BM, a pattern that is most evident in cal3 and BEAST2 tree samples.

4. Discussion

While the Bayesian tip-dating analyses return broadly similar phylogenies, the contrast in topology, divergence dates and model support patterns between approaches suggests that workers need to carefully evaluate the models and priors applied, and the plausibility of complex models when data-sets are limited [20]. Tip-dating methods appear to favour divergence dates that are several Ma older than the minimum age, sometimes tens of millions of years (figure 1 and electronic supplementary material, figures S1–S2). One explanation may be that by treating taxa in tip-dating analyses as single tips (i.e. a single point occurrence), even though more than 20% are known from multiple occurrences across millions of years, the inferred level of sampling may be so low that the average morphological clock rate dominates, swamping increases in the rate of character change and erroneously leading to older dates. The differences between MrBayes and BEAST2 SA-BDSS analyses are difficult to explain given their congruence in a previous comparison (electronic supplementary material, table S3 in [10]). As that study had both extant and extinct taxa, our discrepancy might be due to MrBayes having poor MCMC mixing when all tips are extinct.

Our comparative analyses support previous findings of constrained body-size evolution [18], but there is variation among dating methods in the relative support for OU across trees. Variation in model support among sampled posterior trees reinforces the importance of not taking a single point estimate of phylogeny for downstream analyses [21], and highlights the need to evaluate dated phylogenies from multiple approaches. Future studies should investigate body-size evolution through additional analyses than model choice [22], particularly given the known bias of some dating methods toward supporting OU [23]. The similarity of cal3 and the BEAST2 comparative analyses suggests that cal3 may be a suitable alternative when tip-dating is inapplicable.
Palaeobiologists will likely become major users of tip-dating and probabilistic APT approaches to generate dated phylogenies, replacing the arbitrary APT approaches. However, these techniques are still maturing. Careful consideration and applying multiple dating approaches may be necessary to isolate artefacts and identify what consensus does exist across models and implementations.

Data accessibility. All data, input files and programming scripts for recreating all analyses and figures can be found (separate from the electronic supplementary material) at the Dryad Digital Repository: http://dx.doi.org/10.5061/dryad.n2g80.
