In Japan, pea aphids Acyrthosiphon pism mainly feed on vetch and clover, and many aphid clones produce more progeny on vetch than on clover. In this context, particular genotypes of the facultative symbiont Regiella insecticola enhance reproduction of infected pea aphids specifically on clover, thereby broadening the suitable food plant range of the insect. A species that is sympatric to A. pism, vetch aphids Megoura crassicauda, are commonly found on vetch but not on clover. Laboratory rearing of M. crassicauda strains revealed active reproduction on vetch but substantially no reproduction on clover. Experimental transfection of Regiella from A. pism to M. crassicauda by haemolymph injection established stable and heritable infection in the recipients, although no Regiella infection has been detected in natural populations of M. crassicauda. Different strains of Regiella-infected M. crassicauda grew and reproduced on vetch, but exhibited lower fitness in comparison with corresponding uninfected aphid strains. Strikingly, the Regiella-transfected M. crassicauda exhibited improved survival and some reproduction on clover. These results suggest that Regiella has the potential to confer an ecological trait, adaptation to clover, on novel insect hosts, and also account for why Regiella is able to infect M. crassicauda but is scarcely found in these aphid populations.

2. MATERIAL AND METHODS

(a) Insects
Three isofemale strains of vetch aphid M. crassicauda, namely HGm, TSKm and KKm, were collected from vetch Vicia sativa at three localities in Japan: Hongo, Tokyo, in 1999; Tsukuba, Ibaraki, in 1999; and Kyoto, Kyoto, in 2004. Diagnostic PCR and 16S rRNA gene cloning and sequencing confirmed that these strains harboured the obligate endosymbiont B. aphidicola but no facultative symbionts. A Regiella-infected strain, TUt, of pea aphid A. pism was used as a donor of Regiella, wherein Regiella infection caused enhanced host fecundity specifically on white clover Trifolium repens [12]. A Regiella-cured strain of the same genotype, TUt-m, was also used. These aphid strains were maintained on seedlings of the broad bean Vicia faba at 20°C in a long-day regimen (16 L : 8 D).

(b) Symbiont transfection
Regiella-infected strains of M. crassicauda were established by haemolymph transfer as described [13]. In short, haemolymph from adult TUt insects was injected into CO2-anæsthetized third-instar HGm, TSKm and KKm insects using a glass capillary under a dissection microscope. Haemolymph of the Regiella-cured strain TUt-m was used for control treatments. From 11–13 days after injection, nymphs of the injected insects were collected and individually reared to adulthood on broad bean plants. After collecting a sufficient number of nymphs, the adult insects were subjected to diagnostic PCR for detection of Regiella and Buchnera infections as described [13]. The Regiella-infected and uninfected aphid lines were maintained on seedlings of broad bean, and were regularly checked for Regiella infection by diagnostic PCR.

(c) Plants
Broad bean plants were used two to three weeks after sowing. Vetch and clover plants were grown from field-collected seeds and used as pre-flowering plants three to four weeks after sowing. The plants were grown on medium nutrient compost at 20°C in a long-day regimen (16 L : 8 D).
Table 1. Fitness effects of Regiella infection on M. crassicauda reared on broad bean and vetch. Asterisks indicate statistically significant differences between Regiella-infected and uninfected insects of the same genotype (*p < 0.05, Mann–Whitney’s U-test).

d Fitness measurement
Fitness measurements were conducted 31 months for HGm (equivalent to about 94 generations), 23 months for KKm (about 70 generations) and 24 months for TSKm (about 73 generations) after the injection treatments. In all the transfected aphid strains, Regiella infection was stably maintained during the period. Unwinged aphids were subjected to the experiments. In order to minimize winged morph production, a limited number of aphids (ca 10) were maintained on a seedling of broad bean in each rearing cage. Ten-day-old adult aphids were allowed to deposit nymphs for 6 h, and the newborn nymphs were defined as 0 day old and individually transferred to a new plant of broad bean or vetch. Fresh body weight, pre-reproductive period, number of offspring and longevity of the insects were monitored every day. To examine the aphid performance on clover, the nymphs produced on broad bean plants within 6 h were kept on the same plants for 3 days. In 3-day-old aphids, presumptive unwinged nymphs and presumptive winged nymphs are distinguishable by the absence and presence of wing-pads on their thorax using a dissection microscope. After removing insects with wing-pads, the remaining unwinged-to-be nymphs were transferred to rearing cages with clover plants in 10 groups of 10 individuals for each of the Regiella-infected aphid strains and the uninfected aphid strains. For each of the rearing cages, longevity of the insects was monitored every day, and, if larviposition occurred, the nymphs were counted and then removed. All the experiments were conducted at 20°C in a long-day regimen (16 L: 8 D). The plants were replaced by fresh ones every week.

3. RESULTS AND DISCUSSION

(a) Fitness cost of Regiella infection in M. crassicauda on laboratory host plant V. faba
On broad bean V. faba, all the three genotypes of M. crassicauda, namely HGm, KKm and TSKm, grew well and reproduced actively. Fitness parameters for the Regiella-infected strains were generally equivalent or inferior to those with the uninfected strains of the same genotype. Significant reductions were identified in fecundity in HGm and KKm, and longevity in HGm (table 1).

(b) Fitness cost of Regiella infection in M. crassicauda on native host plant V. sativa
On vetch V. sativa, all the three genotypes of M. crassicauda grew well and actively reproduced, although their fitness values were generally lower than those attained on broad bean. Fitness parameters with the Regiella-infected strains were generally equivalent or inferior to those with the uninfected strains of the same genotype. Significant reductions were identified in pre-reproductive period in HGm, fecundity in HGm and longevity in HGm, KKm and TSKm (table 1).

(c) Megoura crassicauda quickly died on non-host plant T. repens, but Regiella infection improved survival and reproduction on the plant
On clover T. repens, all the three genotypes of M. crassicauda died promptly; nearly 80 per cent of the insects died within 2 days after transfer onto clover plants. However, a small fraction of the insects managed to survive for up to 21 days for HGm, 11 days for KKm and 42 days for TSKm (figure 1). The Regiella-infected strains generally exhibited better survival on clover than the uninfected strains of the same genotype. Significant differences were detected in the strains HGm and TSKm (figure 1a,c). Strikingly, although very small in number, two of the three Regiella-infected strains managed to produce some offspring on clover (figure 2). For the HGm genotype, four and 20 nymphs were produced in two of 10 clover cages with Regiella-infected insects while no reproduction was observed with uninfected insects (figure 2a). For the TSKm genotype, 11, 18, 25 and 60 nymphs were produced in four of 10 clover cages with Regiella-infected insects, whereas 20 and 45 nymphs were produced in two of 10 clover cages with uninfected insects (figure 2c).

(d) Regiella transfection to M. crassicauda conferred potential ability to survive and reproduce on non-host plant
These results illuminate an intriguing biological consequence of the Regiella transfection to vetch aphid M. crassicauda. Originally, M. crassicauda is almost unable to survive and reproduce on clover. However, upon Regiella transfection, their survival and reproduction on the non-host plant are slightly but significantly improved. Considering that the Regiella strain used in

this study improves fecundity of *A. pism* specifically on clover [12], these results can be interpreted as the transfer of an ecological trait, viability on clover, from *A. pism* to *M. crassicauda* by symbiont transfec-

4. CONCLUSION AND PERSPECTIVE

The fitness data of Regiella-infected insects in this study, namely slightly negative effects on the native host plant *V. sativa* and only marginal positive effects on the non-host plant *T. repens*, account for the reason why *Regiella* can potentially be a symbiont of *M. crassicauda* but is scarcely found in natural popu-

this study improves fecundity of *A. pism* specifically on clover [12], these results can be interpreted as the transfer of an ecological trait, viability on clover, from *A. pism* to *M. crassicauda* by symbiont transfec-

Recently, a number of studies have demonstrated environment-dependent fitness advantages conferred by facultative symbionts, and the possibility has been argued that such ecological traits might be moving around between different species in association with horizontal symbiont transfers (reviewed in [2]). Our study suggests that symbiont-mediated acquisition of a novel host plant is not only theoretically but also practically feasible.
evolutionary dynamics of these ecologically important traits in natural aphid populations.
