African grey parrots (Psittacus erithacus) use inference by exclusion to find hidden food

Exclusion allows the detection of hidden food when confronted with the choice between an empty and a potentially baited food location. However, exclusion may be based on avoidance of the empty location without drawing inferences about the presence of the food in the baited location. So far, such inferences have been demonstrated in the great apes only: after seeing an experimenter eating one of two food types, which both had been hidden previously in two boxes, the apes were able to choose the box that still contained the other food type. African grey parrots are capable of exclusion, and we here assessed if they are capable of inference by exclusion. In our task, two different but equally preferred food items were hidden in full view of the birds under two opaque cups. Then, an experimenter secretly removed one food type and showed it to the bird. Similarly to the apes, one out of seven parrots significantly preferred the baited cup; control conditions rule out that its choice was based on associative learning or the use of olfactory cues. Thus, we conclude that—like the apes—some grey parrots are able to infer the location of a hidden food reward.

Keywords: African grey parrots; inference by exclusion; reasoning

1. INTRODUCTION

Choice by exclusion is defined as ‘the ability to base the choice of a target on the rejection of potential alternatives’ [1]; for instance, apes [2], monkeys [3–6], dogs [7–9] and ravens [10] selected the baited box in a two-choice procedure with two opaque boxes after they received information about the empty box only. However, this task can be solved by an avoidance of the empty box rather than an inference about the reward in the baited box. Only in a chimpanzee study by Premack & Premack [11], was it possible to rule out avoidance of the incorrect alternative. First, the experimenter hid an apple and a banana in two different boxes in full view of the ape; subsequently, the chimpanzee was allowed to witness the experimenter eating one of the fruits, which had been removed secretly, and was therefore allowed to choose one box. Only one out of five individuals was reliably able to choose the still-baited box. This task was then replicated with all great ape species by Call [12], who found a similar degree of inter-individual differences. Thus, in general, great apes are able to draw inferences by exclusion, but it seems to be a demanding, not easy-to-solve task.

Nothing is known about ‘true’ inferential reasoning in such a food-finding task beyond the great apes, as it has never been replicated with a non-ape species. Recent data indicate that African grey parrots (Psittacus erithacus), who are well-known for their advanced cognitive abilities [13], are able to choose by exclusion in the visible as well as in the acoustic domain [14]. Therefore, we here tested whether African grey parrots are capable of ape-like true inferential reasoning, which will be important for our understanding of the cognitive evolution of mammals and birds.

2. MATERIAL AND METHODS

The subjects were seven grey parrots (four males), housed in a parrot rescue centre in Vienna, Austria. The birds were of different and often not fully known history and were between approximately 7 and 25 years old. They were housed together with other not tested individuals in an indoor–outdoor aviary (3 × 5 m each) that was enriched with several perches and toys. Birds were fed with fruits in the morning and seeds in the evening. Testing was conducted between 9.00 and 13.00 h and each bird was tested in visual isolation (testing compartment: 120 × 70 cm and 210 cm height) on a fixed platform (60 × 35 cm at a height of 130 cm). The experimental set-up consisted of two identical opaque cups (9 cm height and 8 cm diameter) on a wooden, movable platform (40 × 23 cm) hanging from the ceiling at the same height but 15 cm away from the fixed platform (see electronic supplementary material, figure S1). Therefore, while the birds were positioned on the fixed platform, the experimenter could present the set-up out of their reach on the movable platform and could push it within their reach to allow them to choose.

(a) Pre-tests

(i) Choice training

This test was introduced to ensure that the birds were aware that they would have to make a choice. One type of food (e.g. a seed or a piece of walnut, depending on known preferences of the birds) was placed on the movable platform and covered with an opaque cup. Simultaneously, the second cup was placed on the same platform at a distance of approximately 20 cm. Then, the platform was pushed forward to allow the bird to make a choice by touching a cup with its beak and retrieve a food item if correct. One session consisted of 10 trials; the training criterion to reach the next step was set to be correct on at least eight trials in two consecutive sessions.

(ii) Preference test

This test was introduced to ensure that the test performance would not be influenced by food preferences. We visibly placed two different food items (the same as in the training) simultaneously on the movable platform and covered them with the two cups. Then, the bird was allowed to choose and retrieve one food item. The position of the food types was semi-randomized with the stipulation that the same food type was not placed on the same side for more than three consecutive trials. Two sessions were conducted, each consisting of 10 trials. Birds were advanced to the test if they did not show a preference for one food type, i.e. did not select one item more than 13 times over the two sessions.

(b) Tests

In the test phase, these two equally preferred food items were then placed simultaneously on the movable platform and covered with the two cups.

(i) Visible condition

Standing equidistantly between the cups and in full view of the subjects, the experimenter looked straight ahead, lifted the left cup,

they are capable of true inferential reasoning. However, whereas several subjects solved the task when they could see the experimenter’s actions, only one individual was able to solve the task when it had to infer the outcome of the experimenter’s actions; still, these findings are in line with the inter-individual differences found in the great apes [2,11]. The birds were clearly motivated to obtain the reward, even though side biases occurred (see the electronic supplementary material). As they were highly attentive and never refrained from making a choice, we are confident that the success of only a single bird in the invisible condition is not owing to motivational issues; rather, it supports the assumption that these inference tasks are not trivial but cognitively demanding. Again, this result demonstrates substantial inter-individual differences in grey parrot cognitive performance [15] and that the level of performance depends on subtle differences between tasks [13,16].

Importantly, the successful bird significantly improved her performance only within the invisible condition. This improvement does not necessarily point to associative learning, as the bird performed at chance level in the association control. We suggest that the improvement is owing to the fact that the bird did not comprehend the relevance of the food presentation at the beginning of the test. This is plausible in particular because this bird
was first tested in the invisible condition. Probably, the bird needed a few trials to become acquainted with the test. Thus, we suggest that this bird’s performance was not based on learning instead of reasoning, but rather that the bird learned to reason about the experimenter’s action to solve the task.

The experiments comply with Austrian law.

The authors thank the FWF (P20528-B17) for funding. Special thanks to Nadja Ziegler and the ARGE Papageienschutz for granting access to their grey parrots. Not the least, we thank all the animal keepers and especially Judith Schmidt.
