To avoid collisions when navigating through cluttered environments, flying insects must control their flight so that their sensory systems have time to detect obstacles and avoid them. To do this, day-active insects rely primarily on the pattern of apparent motion generated on the retina during flight (optic flow). However, many flying insects are active at night, when obtaining reliable visual information for flight control presents much more of a challenge. To assess whether nocturnal flying insects also rely on optic flow cues to control flight in dim light, we recorded flights of the nocturnal neotropical sweat bee, *Megalopta genalis*, flying along an experimental tunnel when: (i) the visual texture on each wall generated strong horizontal (front-to-back) optic flow cues, (ii) the texture on only one wall generated these cues, and (iii) horizontal optic flow cues were removed from both walls. We find that *Megalopta* increase their groundspeed when horizontal motion cues in the tunnel are reduced (conditions (ii) and (iii)). However, differences in the amount of horizontal optic flow on each wall of the tunnel (condition (ii)) do not affect the centred position of the bee within the flight tunnel. To better understand the behavioural response of *Megalopta*, we repeated the experiments on day-active bumble-bees (*Bombus terrestris*). Overall, our findings demonstrate that despite the limitations imposed by dim light, *Megalopta*—like their day-active relatives—rely heavily on vision to control flight, but that they use visual cues in a different manner from diurnal insects.

1. INTRODUCTION
Nocturnal sweat bees, *Megalopta genalis* (Halictidae), live in hollowed-out sticks in the tangled understories of neotropical rainforests and are active in the dim light conditions that occur just before sunrise and after sunset [1,2]. To forage, these bees must negotiate the dark and cluttered environment around their nests, flying nearer to the surface that provides the least resistance measurements. When the rate of horizontal optic flow experienced on each eye becomes imbalanced, the insect attempts to restore the balance by flying nearer to the surface that provides the least horizontal optic flow.

As light intensity decreases, however, the perception of the pattern of visual motion is corrupted by noise and becomes decreasingly reliable. Do insects that are active in dim light also rely on optic flow to control flight, despite the reduced reliability of visual information? Here, we explore the limits of dim light vision by investigating whether *Megalopta* flying at low light intensities are also able to use optic flow cues for groundspeed control and centring. We also compare the visual flight-control strategies of *Megalopta* and a diurnal bee, *Bombus terrestris* (Apidae).

2. MATERIAL AND METHODS
Nest sticks of *M. genalis* were collected on Barro Colorado Island in Panama and transferred to the experimental site (see [1] for site description). To explore the differences between the visual flight-control strategy of *Megalopta* and a day-active hymenopteran, we repeated the experiment using *B. terrestris* from a commercial hive (Koppert, UK) located outdoors near Lund, Sweden.

The experimental set-up consisted of a Perspex tunnel, 14 cm wide × 14.5 cm high × 50 cm long, mounted 65 cm above the ground. The nest/hive was placed at an opening in one end of the tunnel such that, to exit or enter their nest/hive, the bees had to fly along the tunnel's length. The walls of the tunnel were lined with either a pattern consisting of randomly placed black-and-white 3 × 3 cm squares ('check'), or a pattern of alternating black-and-white 3 cm wide horizontal stripes ('stripe'). For a bee flying along the tunnel, the check pattern provided strong horizontal optic flow cues, whereas the stripe pattern provided minimal horizontal visual cues. The effect of horizontal optic flow cues on flight control was tested under three conditions: (i) check/check—both walls displayed the check pattern, (ii) check/stripes—one wall displayed the check pattern and one displayed the stripe pattern, and (iii) stripe/stripes—both walls displayed the stripe pattern. The three conditions were presented to the bees in a randomized order, with each condition being presented four times. The numbers of recorded flights were 24 and 28 (check/check), 21 and 32 (check/stripes), 24 and 31 (stripe/stripes), for *Megalopta* and *Bombus*, respectively.

To avoid collisions when navigating through cluttered environments, flying insects must control their flight so that their sensory systems have time to detect obstacles and avoid them. To do this, day-active insects rely primarily on the pattern of apparent motion generated on the retina during flight (optic flow). However, many flying insects are active at night, when obtaining reliable visual information for flight control presents much more of a challenge.
Interestingly, in all conditions, the diurnal bumble-bees fly considerably faster than *Megalopta* (figure 1). Like *Megalopta*, bumble-bees increase their ground-speed when horizontal motion cues are minimized (figure 1; stripe/stripe compared with check/check condition: $t_{57} = 8.11$, $p < 0.0001$). Unlike *Megalopta*, however, bumble-bees do not fly faster when horizontal motion cues are removed from only one wall (check/stripe compared with check/check condition: $t_{58} = 0.78$, $p = 0.44$). Another difference between *Megalopta* and bumble-bees is the effect of horizontal motion cues on centring. Whereas an asymmetry in horizontal optic flow did not affect centring in *Megalopta*, it caused the bumble-bees to fly closer to the wall that displayed the stripe pattern in the check/stripe condition (figure 2b; comparison with check/check condition: $t_{58} = 6.68$, $p < 0.0001$). There was no difference in the average distance from the midline between the stripe/stripe and the check/check conditions in bumble-bees ($t_{57} = -0.75$, $p = 0.46$).

4. DISCUSSION

In this study, we compared the flight control of two different bee species adapted for flight at radically different light intensities. The most striking result of this comparison is the difference in the speed at which *Megalopta* and bumble-bees fly. When optic flow cues are strong, the mean groundspeed of bumble-bees in the tunnel is over five times faster than that of *Megalopta*. One way to improve visual reliability in dim light is to integrate the visual signal over time; a process called temporal summation. A consequence of temporal summation is the inability to detect high rates of optic flow, so the animal has to reduce its speed in order to perceive self-generated visual motion. The relatively low groundspeed of *Megalopta* lends support to the behavioural [14] and theoretical [15] indications that these bees use temporal summation to help them to perceive optic flow and to use it for flight control.

Further evidence for the importance of vision for flight control in *Megalopta* is provided by the finding that groundspeed increases when optic flow cues are minimized. This response is similar to the behaviour of honeybees [5,6] and bumble-bees [8,11], indicating that optic flow information is used in a similar manner for groundspeed control. However, other observed differences between the flight-control behaviours of *Megalopta* and bumble-bees suggest that *Megalopta* is using optic flow information in a different way to control flight. For example, in the check/stripe condition, bumble-bees fly closer to the stripe pattern in an apparent attempt to balance the optic flow experienced in each eye. We see no such effect in *Megalopta*. Groundspeed also increases in *Megalopta* in the check/stripe condition, even though they are maintaining the same distance from each wall. The differences in behaviour that we observe may be because *Megalopta* use optic flow cues from different parts of the visual field, such as the dorsal or ventral regions, to maintain a safe distance from nearby obstacles and to control groundspeed, or because they have reduced their reliance upon vision for flight control in favour

3. RESULTS

When the patterns on the walls of the tunnel provided decreasing amounts of horizontal optic flow cues—check/check, and stripe/stripe condition in comparison with the check/check condition—groundspeed in *Megalopta* increased (figure 1; check/stripe condition: $t_{43} = 3.30$, $p = 0.002$; stripe/stripe condition: $t_{46} = 7.81$, $p < 0.0001$). However, the amount of horizontal optic flow present in the tunnel had no effect upon the average centring (lateral position) of the bees as they flew along the tunnel (figure 2a; one-way ANOVA: $F_{2/66} = 0.79$, $p = 0.46$).

*Biol. Lett.* (2011)
of information that is not affected by light intensity, such as mechanosensory measurements of airspeed.

It is interesting to note that, when horizontal optic flow cues are strong, *Megalopta* show more variation in lateral position than bumble-bees. This may be owing to differences in the flight performance of the two species, but another possibility is that the sensory information which *Megalopta* uses to maintain a constant distance between the tunnel walls is noisier or less reliable than the information being used by the bumble-bees.

Overall, the results of this study demonstrate that the visual system of a nocturnal insect is capable of detecting optic flow information in dim light and using it for flight control. This is remarkable considering the sensory challenge of controlling flight in the complex environment of a dark rainforest.
