Because arbuscular mycorrhizal fungal (AMF) species differ in stimulating the growth of particular host plant species, AMF species may vary in their effects on plant growth stimulation [4], and because mycorrhizal different AMF species often vary in host plant mortality and growth response to colonization. We also found a positive correlation between mortality and growth response to colonization. Our results demonstrate that AMF species can affect plant mortality and the self-thinning process by affecting plant growth differently.

Keywords: arbuscular mycorrhizal fungi; Medicago sativa L.; plant mortality; plant self-thinning

1. INTRODUCTION

It has been widely recognized that arbuscular mycorrhizal fungi (AMF) can influence plant interactions and plant population dynamics [1]. Intra-specific competition was higher with AMF than without in non-self-thinning plant populations [1,2]. In self-thinning plant populations, AMF were reported to have little effect on plant competition [3]. Because different AMF species often vary in host plant growth stimulation [4], and because mycorrhizal fungal communities often vary in species composition, the influence of AMF identity on plant–plant interactions warrants elucidation if we are to understand the role of diverse mycorrhizal fungal communities in nature. Although Hoeksema [5] has found that plant intra-specific competition varied with different ectomycorrhizal fungal species, there is no published examination of the effect of different AMF identities on self-thinning.

Self-thinning is a phenomenon whereby as a crowded stand of plants develops, some individuals die, while others grow. In a self-thinning population, mortality originates from intra-specific competition for limiting resources (such as light). In theory, the larger the plants are, the more intensive the competition would be for limiting resources. Thus, AMF identity could influence mortality through influencing host plant size. Here we used a legume plant Medicago sativa L. and four common indigenous AMF species to test this hypothesis.

2. MATERIAL AND METHODS

(a) Experimental design

The soil used here is the same as that in a previous study [6]. The legume plant M. sativa L. was used as model plant because it strongly depends on AMF [7]. Four indigenous AMF species (Glomus versiforme, Glomus diaphanum, Glomus geosporum and Glomus etunicatum) [8] were used in this experiment.

AMF species was one factor in this experiment, and plant density was another. Microcosms (14 × 13 × 15 cm) were filled with 3 kg of soil. Spores of the four different AMF species were inoculated into each microcosm (n = 8 microcosms per AMF species). For the non-mycorrhizal control (n = 8 microcosms), washing filtrate and the sterilized leftover of the inoculum were added to correct for possible differences in the microbial community between mycorrhizal and non-mycorrhizal treatments.

We set up two densities in this study. For the low density, one seedling of M. sativa was kept in each microcosm (LD). For the high density, 250 seeds of M. sativa were sown for each microcosm. Before sowing, a thin layer of soil was sieved over the microcosms to provide a smooth surface to minimize spatial heterogeneity. Seeds were mixed with sand and sown with a sieve to achieve a random spatial pattern, with a density equal to 10 000 plants per square metre (HD). Within each AMF species identity treatment, four replicates were used for the low density and high density, respectively, to achieve a total of 40 microcosms. All microcosms were arranged in a completely randomized design under greenhouse conditions from April to September in 2008 (see electronic supplementary material for more detailed information about experimental design).

Plants were harvested after seedling emergence, when high-density plant populations had experienced a self-thinning process and most of the large individuals had flowered. Mortality was apparently randomly distributed across the area of the high-density populations. Above-ground plant biomass and surviving plant numbers in high density were recorded. Root systems were collected and cleaned for AM colonization detection by the gridline intersection method [9].

(b) Data analysis

Mortality was calculated as: mortality (%) = (initial plant density – final plant density)/initial plant density × 100%.

For the high-density treatment, as one of the four replicates was destroyed during the experiment, we used the data of three replicates for the analysis. For the low-density and high-density datasets separately, one-way ANOVA was performed to test for the effects of AMF species identity on AM colonization rate, shoot biomass, plant number and mortality in DPS software [10]. Least significant difference at the 5 per cent alpha level was used for comparison between treatments. Normality and homogeneity of variances were tested before ANOVA. We performed linear regression modelling to test the relationship between shoot biomass and colonization rate with the data from the four mycorrhizal treatments (non-mycorrhizal control data were not included) in both densities. The relationship between mortality and mean shoot biomass was also tested in the high density with all the five mycorrhizal treatment data included. We also used linear regression to test the relationship between mean shoot biomass for each species treatment in the high density and mean shoot biomass for each species identity in low density.

3. RESULTS

At low density, AM colonization and shoot biomass were significantly different among AMF treatments (table 1), including differences in shoot mass among different AMF species. In the non-mycorrhizal control, no mycorrhizal colonization was detected. At high density, mortality and mean shoot biomass varied with AMF identities (table 1). Plant growth and mortality were highest with G. diaphanum (table 1). Glomus versiforme had no significant effect on plant growth and mortality when compared with non-mycorrhizal control (table 1).

In the high-density population, a significantly positive relationship was found between mortality and mean shoot biomass (figure 1). The fungus *G. diaphanum* promoted plant growth more than the other fungi whenever the host plant was grown individually (table 1 and figure 2) or in self-thinning populations (table 1), and plant mortality was the highest when inoculated with this fungus (table 1 and figure 1). A significantly positive relationship was also found between mean shoot biomass in high densities and mean shoot biomass when grown individually (figure 2). The relationship between shoot biomass and colonization rate was not significant under both densities (for LD: $r^2 = 0.031$, $p = 0.511$; for HD: $r^2 = 0.0016$, $p = 0.901$).

### 4. DISCUSSION

The effects of host–fungi partnerships vary with AMF species. For example, AMF species vary in their ability to acquire resources below ground [11] and to stimulate host plant growth [4]. These differential growth responses of plant species to AMF species may shift the balance of interspecific plant interactions and influence plant community structure [4,12,13]. In our experiment, we found that AMF identities also affected plant mortality in a self-thinning experimental population of *M. sativa*. Plant mortality during the self-thinning process is often explained by intra-specific competition for limiting resources, usually light or space. AMF have been shown to increase mortality by increasing host plant growth and branching, and have no effect on mortality when plant growth was not affected [3]. Hoeksema [5] also reported that plant intra-specific competition was stronger when colonized with the ectomycorrhizal fungus that caused a higher plant growth rate. Here we found that AMF identities affected plant mortality differently, by affecting plant growth differently. For example, *G. diaphanum* promoted plant growth more than the other mycorrhizal fungi did when plants were grown individually (table 1), and this growth stimulation generated a higher mortality rate (table 1) during self-thinning, probably owing to higher shoot competition. In contrast, *G. versiforme*...
did not influence mortality when compared with non-mycorrhizal controls, as it had no effect on plant growth.

As smaller individuals usually die first during self-thinning, variable AMF species effects on mortality could have long-term consequences for plant population dynamics. When mycorrhizal fungi promote self-thinning, they are selecting for plants that are particularly responsive to mycorrhizal colonization. Therefore, it seems that the mycorrhizal fungi that promote growth the most are imposing more selection than fungi that do not promote growth as much. When a host plant population encounters an AMF community with a preferred dominant species, plant individuals will grow faster than with an AMF community dominated by species that are not preferred. In the former population, smaller individuals would tend to suffer more seriously from competition pressure, and the onset of self-thinning would appear earlier. It is also clear that these plant populations would suffer the most substantial mortality even with growing of larger individuals. This process would produce fewer, larger individuals within these plant populations. Sometimes small plants are small owing to random events, but sometimes small plants are small owing to genetic variation [14]. This suggests that, in a community where G. diaphanum was dominant, natural selection might occur over time for the genes that confer on the plants greater responsiveness to colonization. However, in a community where G. versiforme was dominant, there would be no selection for the genes that confer greater responsiveness to colonization.

Distributions patterns (random or uniform) can strongly impact plant interactions [15]. In our study, we examined these effects of AMF identities in a random distribution pattern. It is worth elucidating the role of AMF identities on plant interactions under a uniform pattern of plant distribution, as this may help explain the role of AMF in agricultural systems [16], where plant distribution is usually in a uniform pattern or in a regular row [17].

As only four AM fungi and one self-thinning density were used in this experiment, these results need to be corroborated by further studies with more AMF species and a wider range of plant densities. Overall, our study showed that different AMF identities induced different self-thinning rates through influencing plant growth, and that AMF species that promoted plant growth most are also those that increased mortality the most. These results provided direct evidence that variation in AMF species effects on plant growth can induce variation in plant population dynamics, advancing our knowledge of how AMF community composition may affect plant populations.
